Key words: coagulation parameter; D-dimer; viscoelastic tests; COVID-19; ARDS

Abstract

Background: Few observations exist with respect to the pro-coagulant profile of patients with COVID-19 acute respiratory distress syndrome (ARDS). Reports of thromboembolic complications are scarce but suggestive for a clinical relevance of the problem. Objectives. Prospective observational study aimed to characterize the coagulation profile of COVID-19 ARDS patients with standard and viscoelastic coagulation tests, and to evaluate their changes after establishment of an aggressive thromboprophylaxis. *Methods:* Sixteen patients with COVID-19 ARDS received a complete coagulation profile at the admission in the intensive care unit. Ten patients were followed in the subsequent 7 days, after increasing the dose of low molecular weight heparin, antithrombin levels correction, and clopidogrel in selected cases. Results: At baseline, the patients showed a pro-coagulant profile characterized by an increased clot strength (CS, median 55 hPa, 95% interquartile range 35-63), platelet contribution to CS (PCS, 43 hPa, interquartile range 24-45), fibrinogen contribution to CS (FCS, 12 hPa, interquartile range 6-13.5 elevated D-dimer levels (5.5 µg/mL, interquartile range 2.5-6.5), hyperfibrinogenemia (794 mg/dL, interquartile range 583-933). Fibrinogen levels were associated (R²=0.506, P=0.003) with interleukin-6 values. After increasing the thromboprophylaxis, there was a

significant (P=0.001) time-related decrease of fibrinogen levels, D-dimers (P=0.017), CS (P=0.013), PCS (P=0.035) and FCS (P=0.038). *Conclusion.* The pro-coagulant pattern of these patients may justify the clinical reports of thromboembolic complications (pulmonary embolism) during the course of the disease. Further studies are needed to assess the best prophylaxis and treatment of this condition.

Introduction

Patients with COVID-19 associated pneumonia exhibit a number of abnormal coagulation parameters, according to different reports,¹⁻³ and coagulation abnormalities have been associated with a higher mortality rate.³⁻⁵ The hemostatic system alterations include changes in the activated partial thromboplastin time (aPTT), in the international normalized ratio (INR) of the prothrombin time, increased D-dimer and fibrin degradation products (FDP). The aPTT and the prothrombin time were found shorter than normal in 16% and 30% of the patients, respectively.² Patterns of disseminated intravascular coagulation (DIC) were reported in deaths, and within this group the aPTT and the prothrombin time were prolonged.³

In our Intensive Care Unit (ICU) we started admitting patients with COVID-19 infection and acute respiratory distress syndrome (ARDS) since March 8th. In the first two days, we had two mortality cases with a pattern of pulmonary embolism (sudden death after mobilization with signs of acute right ventricular failure), and other Hospitals in our network reported similar cases. Pulmonary embolism cases in COVID-19 patients have already been reported in literature⁶, and in a recent report from EuroELSO, 20% of patients under extracorporeal membrane oxygenation had pulmonary embolism.⁷ From 2 to 5 days after the first admission in the ICU we have started a wide collection of laboratory data and coagulation point-of-care tests viscoelastic tests to characterize the coagulation profile of these patients. Additionally, after the first round of tests, we have changed our standard anticoagulant therapy toward a higher degree of anticoagulation. In this study is, the coagulation profile of COVID-19 ARDS patients is analyzed with standard tests and visco-elastic tests, and the differences induced by a more aggressive antithrombotic therapy are investigated.

Methods

Patient population

The patient population comprised 16 patients with a diagnosis of COVID-19 associated pneumonia and ARDS, admitted to our ICU under tracheal intubation and mechanical ventilation. The study was approved by the Ethics Committee of the San Raffaele Hospital. Data are presented in an anonymous form.

Central laboratory and point-of-care coagulation tests

The hemostatis and coagulation characterization included the measure of the aPTT, INR, platelet count, fibrinogen, D-dimer, antithrombin (AT) activity. INR and aPTT were assessed using respectively the STA-NeoPTimal 10 and the STA-Cephascreen 10 (Diagnostica Stago, Asnières sur Seine, France); fibrinogen was measured using the Clauss-based STA-LiquidFib (Diagnostica Stago, Asnières sur Seine, France). Cytokine levels (interleukin-6, IL-6) were measured at the admission in the ICU.

Viscoelastic tests were performed after 2-5 days from the admission in the ICU. We have used a Quantra Hemostasis analyser (Quantra[®] System, HemoSonics LLC,

Charlottesville, VA), that utilizes an ultrasound-based technology that measures changes in viscoelastic properties of whole blood. The Quantra System includes a consumable cartridge that provides a number of parameters related to clot time and clot stiffness. Blood is collected in citrated tubes and blood is directly suctioned by the instrument, without blood dispersion. This study was performed using the Quantra QPlus[®] cartridge which includes 4 parallel channels, each pre-filled with specific lyophilized reagents and performing simultaneous measurements. The output of the instrument consists of (i) clot coagulation time (CT, seconds) after blood activation with kaolin; (ii) Clot Stiffness (CS, hPa) after activation by thromboplastin (iii) fibrinogen contribution to the overall clot stiffness (FCS, hPa) by adding abciximab (ReoPro, Eli Lilly, Indianapolis, IN); and (iv) Platelet Contribution to CS (PCS, hPa), as difference between the total CS and the FCS.⁸ All the patients received a baseline determination of standard and viscoelastic tests. Ten patients were followed over the next 7 days, with daily measure of standard tests.

Thromboembolic prophylaxis and other therapies

At the ICU admission, all the patients were receiving a thromboprophylaxis management of 4000 IU b.i.d. low molecular weight heparin (LMWH, calcium nandroparine). After the first round of standard coagulation and viscoelastic tests, the patients were switched to the following protocol: LMWH 6000 b.i.d. (8000 IU b.i.d. if body mass index > 35); AT concentrate to correct values < 70%; clopidogrel loading dose 300 mg + 75 mg/day if platelet count > 400,000 cells/ μ L. Additional therapies included hydroxilcholoquine , and anti-viral agents.

All the patients were sedated with propofol or midazolam, and mechanically ventilated under full muscle relaxant dose.

Statistics

Data are presented as number (%), and median (interquartile range) as appropriate. Data were tested for differences at the various points in time using a Friedman test. Correlation between different continuous variables was tested with linear or polynomial regression analyses. For all the tests, a two-tailed P value < 0.05 was considered significant. The statistical analyses were conducted using computerized packages (All the analyses were performed using computerized statistical packages (SPPS 13.0, IBM, Chicago, IL, and GraphPad, San Diego, CA).

Results and discussion

Table 1 reports the baseline characteristics of our patient population at baseline and follow-up. Overall, 94% of the patients were males. Five (31%) were obese, according to the definition of the World Health Organization, and 4 out of 5 had a body mass index > 35. Median values of coagulation parameters showed a prolongation of the aPTT, with platelet count within the normal range and 1 patient with thrombocytosis (472,000 cells/µL). Four patients (25%) had AT levels below the lower limit of the normal range; the median value of fibrinogen was higher than the upper limit of the normal range, and all the patients had values higher than 400 mg/dL. D-dimer and IL6 values were higher than the upper limit of the normal range in all the patients.

Fibrinogen levels were significantly (P=0.003) associated with the IL6 values at baseline, according to a logarithmic regression (R^2 for association = 0.506) (figure 1). Viscoelastic tests showed normal values of CT but confirmed a clot firmness higher than normal, with median values of CT, PCS, and FCS higher than the upper limit of normal range. Eleven (69%) patients had CT values longer than the upper limit of the normal range, with 10 patients (62%) showing PCS values above the upper limit of normal range and 15 (94%) patients with FCS values above the upper limit of the normal range. Nine patients received a second viscoelastic test after 2 weeks from the baseline (figure 2). There was a significant decrease of CS (P=0.013), PCS (P=0.035) and FCS (P=0.038).

Time-related changes in standard coagulation profile are shown in figure 3. Changes in INR and platelet count were non-significant. There was a significant (P=0.012) prolongation of the aPTT, and a significant (P=0.001) decrease of fibrinogen levels and D-Dimers. AT levels significantly (P=0.018) increased, with 2 patients receiving AT concentrate supplementation on day 2.

The main finding of our study is the pro-coagulant profile of COVID-19 ARDS patients and its progression towards normalization after an increased thromboprophylaxis. The baseline pattern of our patient population is an increased clot strength, which in 100% of the patient population was related to high fibrinogen levels, and in about 60% even to an elevated platelet contribution to clot strength.

From an interpretative perspective, this pattern sticks to a model of interaction between inflammation and coagulation. All the patients had elevated values of IL6, and a clear association between IL6 and fibrinogen levels was demonstrated. IL6 is a powerful proinflammatory cytokine, which induces tissue factor (TF) gene expression in endothelial cells and monocytes, fibrinogen synthesis, and platelet production, without affecting fibrinolysis.^{9,10} TF triggers thrombin generation, and the combination of these factors produce a pro-coagulant profile that was evident in our patient population. Unfortunately, we are lacking direct data on thrombin generation, and the different parameters related to clot formation time (aPTT, INR, and CT) basically reflect the ongoing thrombosis prophylaxis/therapy by LMWH. However, the evidence of an AT consumption at baseline is an indirect marker of thrombin generation. D-dimers are certainly non-specific parameters of thrombi formation, but within this pattern they suggest thrombi generation and fibrinolysis.

The establishment of a more pronounced thromboprophylaxis (increased doses of LMWH, AT correction, and clopidogrel in case of thrombocytosis) resulted in a significant

decrease of fibrinogen levels and D-dimers, and of the viscoelastic parameters related to clot strenght.

D-Dimer levels have been identified as markers of severity of the disease⁴ and predictive of mortality.³ The decrease of D-dimers is therefore suggestive of a decrease severity of the disease. Previous studies have stressed a possible transition to a DIC associated with mortality, and in this case, following its natural course, the prothrombotic state is converted into a pro-hemorrhagic pattern.³ In our series, we could not observe a transition toward this state, conversely noticing, after 2 weeks, a return to normal of viscoelastic parameters in the survived patients.

This pattern of prothrombotic coagulopathy is different from what noticed in sepsis, where thrombocyte count is usually decreased, and of DIC, where the exhausted coagulation system shows a prolongation of the prothrombin time and aPTT, and a hemorrhagic tendency. It is possible that the aggressive thromboprophylaxis may have slowed or blocked the transition to DIC, as suggested by the tendency to normalize the coagulation parameters after 7-14 days.

From a clinical perspective, it is nowadays evident that COVID-19 ARDS patients may suffer from thromboembolic complications. Cases of pulmonary embolism (PE) have been published⁶, and a recent report of the French experience with extracorporeal membrane oxygenation in COVID-19 induced ARDS showed 20% of PE events and 2 oxygenator thrombosis. The link between influenza-associated pneumonia and thromboembolic events was already stressed in previous studies.¹¹ Our study, in combination with the other contributions in literature, suggests the potential role of micro/macro-aggregate formation inside the pulmonary vasculature within the pattern of ARDS in COVID-19 patients. This could justify the evidence of a severe impairment of oxygenation, despite a preserved lung compliance (at least in the early stages of the disease).

In our series of 16 patients, after increasing the anticoagulation regimen we did not observe major thromboembolic events. Six (37.5%) patients were extubated and discharged to the ward; 3 (18.7%) are still in the ICU; 7 (43.7%) did not recover and died due to hypoxia and multi-organ failure. An aggressive thromboprophylaxis of these patients seems justified, and the recent guidance of the International Society on Thrombosis and Haemostasis stresses the need for coagulation monitoring and LMWH

therapy.¹² A recent study demonstrated a lower 28-days mortality rate in patients receiving anticoagulation with LMWH.¹³ Other strategies could include the use of intravenous unfractionated heparin or direct thrombin inhibitors (bivalirudin or argatroban).

The main limitations of our study are the small sample size, and the lack of direct data on thrombin generation and fibrinolysis. Being a non-randomized trial, our hypothesis that the patients may benefit from a pronounced anticoagulation needs to be confirmed by adequate randomized controlled trials.

Authors contribution

M.R. designed the study. A.B., Marco Resta, Marco Dei Poli and U.D.D collected the data. E.B. analyzed the viscoelastic tests. M.F. provided the literature search on thromboembolic events imaging and critically revised the manuscript. G.A. designed the study with M.R. L.M. critically revised the manuscript Conflict of interest

M.R. and E.B. received speaker's fees and research funds from Hemonetics. No conflict of interest reported for the other authors.
